Résumé - On calcule pour des noyaux finis, la partie imaginaire du potentiel optique noyau-nucléon sur et hors couche utilisant l'approximation du gaz de Fermi local et une force d'échange à deux corps ayant une portée finie. On compare les résultats avec ceux obtenus par des calculs pour la matière infinie et ceux obtenus soit pour la densité locale soit pour l'approximation de Glauber.

Abstract - We calculate for finite nuclei the imaginary part of the nucleus-nucleon optical potential on and off shell by using the local Fermi gas approximation and a finite range two-body exchange force. Results are compared with those obtained by infinite nuclear matter calculations as well as using the local density or Glauber approximation.

I - INTRODUCTION

The imaginary part of the nucleus-nucleon optical potential enters directly in various quantities of interest in static properties of nuclei or in nuclear reaction theories, e.g. in the effective mass /1/ and the self energy /2-5/, the nucleon mean free path /6-7/ and quasi-particle life times /8/ or in theories of inelastic scattering. Whereas the optical potential has been often calculated fully microscopically, semiclassical calculations exist only for infinite nuclear matter /3,9,10/ or finite nuclei with the local density approximation /5/. The latter approximation consists of replacing the Fermi energy λ by its local equivalent $\epsilon_F(R)$. A review over existing semiclassical calculations is given in ref. /11/.

In this paper we are concerned with finite nuclei and take the finite size effects into account exactly with help of an average nuclear potential $V(R)$ which we need not specify explicitly. Furthermore, we also calculate the off shell behaviour of the optical potential which has often been assumed to be weak /7/. In order to be realistic, we employ a finite range exchange potential which forces the optical potential to decrease at high energies. Results will also be compared with those obtained by use of the Glauber approximation which neglects the Pauli principle. Preliminary results have already been presented in refs. /12,13/.

II - THE MODEL

Beyond Hartree-Fock, the first corrections to the nuclear self energy are given by core polarization and correlation contributions according to Fig. 1.

Fig. 1 - The first three graphs of the nuclear self energy.

Written in terms of the mass operator,

$$M_{AA'}^{\omega} = \frac{1}{2} \bar{v}_{1234} \left\{ \frac{\bar{n}_2 \bar{n}_3 \bar{n}_4}{\omega + \varepsilon_2 - \varepsilon_3 - \varepsilon_4 + i\eta} - \frac{\bar{n}_2 n_3 n_4}{\omega + \varepsilon_2 - \varepsilon_3 - \varepsilon_4 - i\eta} \right\} \bar{v}_{432A'} , \quad (1)$$

where \bar{n} , n and ε are the particle and hole densities and energies, respectively, and \bar{v} is the two-body interaction, one sees that the polarization graph contributes only if the energy ω is above the Fermi energy λ and the correlation graph only if ω is smaller than λ . Rewriting the imaginary part of (1) in space representation, one obtains the nonlocal imaginary part of the optical potential,

$$\begin{aligned} W_{\pi\pi'}^{\omega} = & \frac{\pi}{2} \int_{-\infty}^{+\infty} \frac{dt}{2\pi} e^{i\omega t} \int d^3r_1 d^3r_2 d^3r_3 d^3r'_1 d^3r'_2 d^3r'_3 \\ & \times \bar{v}(r_1 r_2 r_3) \bar{v}(r'_1 r'_2 r'_3) \\ & \times \left[\langle r_1 | \rho e^{iHt} | r'_1 \rangle \langle r_2 | \bar{\rho} e^{-iHt} | r'_2 \rangle \langle r_3 | \bar{\rho} e^{-iHt} | r'_3 \rangle \right. \\ & \left. + \langle r_1 | \bar{\rho} e^{-iHt} | r'_1 \rangle \langle r_2 | \rho e^{iHt} | r'_2 \rangle \langle r_3 | \rho e^{iHt} | r'_3 \rangle \right] . \end{aligned} \quad (2)$$

Here $\bar{\rho}$, ρ and H are the particle and hole density operators and the one particle Hamiltonian, respectively.

In order to obtain the coordinate and momentum dependent optical potential for a contact exchange force

$$\bar{v}(r_1 r_2 r_3) = \bar{v}(|\vec{r} - \vec{r}_1|) \delta(\vec{r} - \vec{r}_2) \delta(\vec{r}_3 - \vec{r}_3) , \quad (3)$$

we go over to relative and center-of-mass coordinates according to

$$\vec{s} = \vec{r} - \vec{r}' \quad \vec{R} = \frac{\vec{r} + \vec{r}'}{2} \quad (4)$$

and Fourier transform with respect to the c.m. coordinates, $\vec{s} \rightarrow \vec{P}$, $\vec{s}_1 \rightarrow \vec{p}_1$. Then the matrix elements in eq. (2) can be written in semiclassical approximation as

$$\langle \vec{r} | \rho e^{iHt} | \vec{r}' \rangle = \int \frac{d^3P}{(2\pi)^3} e^{i\vec{P}\vec{s}} e^{it\left(\frac{P^2}{2m} + V(R)\right)} \theta\left(\lambda - \frac{P^2}{2m} - V(R)\right) \quad (5)$$

and, similarly, for $\bar{\rho} \exp(-iHt)$. This yields

$$\begin{aligned} W(\omega, P, R) = & \frac{\pi}{2} \int_{-\infty}^{+\infty} \frac{dt}{2\pi} \int d^3r_1 \int d^3r'_1 v(|\vec{r} - \vec{r}_1|) v(|\vec{r}' - \vec{r}'_1|) \int d^3s e^{i\vec{s}\vec{P}} \\ & \times \int \frac{d^3p_1}{(2\pi)^3} \int \frac{d^3p_2}{(2\pi)^3} \int \frac{d^3p_3}{(2\pi)^3} e^{i(\vec{p}_1 \vec{s}_1 - \vec{p}_2 \vec{s} - \vec{p}_3 \vec{s}_1)} e^{it\left(\omega + \frac{p_1^2 - p_2^2 - p_3^2}{2m} - V(R)\right)} \\ & \times \left[\theta\left(\lambda - \frac{P^2}{2m} - V(R)\right) \theta\left(\frac{P^2}{2m} + V(R) - \lambda\right) \theta\left(\frac{P^2}{2m} + V(R) - \lambda\right) + \theta_- \theta_- \theta_- \right] , \end{aligned} \quad (6)$$

where θ_- indicates the same step function in the square bracket but taken at negative argument. Now the time and relative coordinate integrations can be performed to give

$$\begin{aligned}
W(\omega, \mathbf{P}, \mathbf{R}) = & \frac{2}{(2\pi)^5} \int d^3 R_1 \int d^3 p_1 \int d^3 p_2 \int d^3 p_3 \\
& \times [\theta(p_F^2(R_1) - p_1^2) \theta(p_2^2 - p_F^2(R)) \theta(p_3^2 - p_F^2(R_1)) + \theta_- \theta_- \theta_-] \\
& \times \delta(\bar{\mathbf{P}} + \bar{\mathbf{p}}_1 - \bar{\mathbf{p}}_2 - \bar{\mathbf{p}}_3) \delta(\omega - \lambda + \varepsilon_F(R) + (p_1^2 - p_2^2 - p_3^2)/2m) \\
& \times \int d^3 x e^{2i(\bar{\mathbf{P}} - \bar{\mathbf{p}}_2)\bar{\mathbf{x}}} v(|\bar{\mathbf{R}} - \bar{\mathbf{R}}_1 + \bar{\mathbf{x}}|) v(|\bar{\mathbf{R}} - \bar{\mathbf{P}}_1 - \bar{\mathbf{x}}|),
\end{aligned} \quad (7)$$

where we have introduced the local Fermi energy and the local Fermi momentum according to

$$\varepsilon_F(R) = \frac{p_F^2(R)}{2m} := \lambda - V(R). \quad (8)$$

In eq. (7) finite size effects enter directly in the energy conserving δ -function by the additional local Fermi energy.

For simplicity, we now use a Gaussian force of range r_0 in coordinate or of range k_0 in momentum space

$$\begin{aligned}
\bar{v}(r) &= v_0 e^{-(r/r_0)^2} \\
\bar{v}(k) &= \frac{v_0}{2\pi^{5/2} k_0^3} e^{-(k/k_0)^2}, \quad k_0 = 2/r_0.
\end{aligned} \quad (9)$$

Then the integration over $\bar{\mathbf{x}}$ in eq. (7) can be performed. Furthermore, the momentum conserving δ -function suggests to introduce the relative and c.m. momentum transfers according to

$$\begin{aligned}
\bar{\mathbf{p}}_1 &= \bar{\mathbf{P}} - \bar{\mathbf{q}}/2 \\
\bar{\mathbf{p}}_2 &= \bar{\mathbf{P}} + \bar{\mathbf{q}}/2 \\
\bar{\mathbf{p}}_3 &= \bar{\mathbf{P}} - \bar{\mathbf{q}}
\end{aligned} \quad (10)$$

and to use the angle convention

$$\begin{aligned}
\bar{\mathbf{P}} \cdot \bar{\mathbf{q}} &= p_z q \\
p^2 &= p_\perp^2 + p_z^2 \\
\bar{\mathbf{P}} \cdot \bar{\mathbf{q}} &= p q \hat{q}
\end{aligned} \quad (11)$$

Then the \hat{q} and p_\perp integrations can be performed to yield the final result

$$\begin{aligned}
W(\omega, \mathbf{P}, \mathbf{R}) \propto & \frac{1}{R} \int_0^{R_0} dR' [e^{-k_0^2(R-R')^2/2} - e^{-k_0^2(R+R')^2/2}] \\
& \times \frac{1}{2P} \int d p_z \int d q q e^{-2q^2/k_0^2} \left[2p_z q \theta(p_F(R') - p_z - \frac{q}{2}) + (p_F^2(R') - (p_z - \frac{q}{2})^2) \theta(p_z + \frac{q}{2} - p_F(R')) \right] \\
& \times \theta(2m|\omega - \lambda| - 2p_z q) \theta(p_F(R') - |p_z - \frac{q}{2}|) \theta(2p_z q - |q|^2 + 2p_z q + p^2 - 2m(\omega - \lambda + \varepsilon_F(R))) \\
& \quad \quad \quad + \text{for } \omega \leq \lambda,
\end{aligned} \quad (12)$$

where R_0 is the turning point at which $V(R_0) = \lambda$.

III - ZERO RANGE FORCE

Eq. (12) simplifies considerably if the range of the force tends to zero or $k \rightarrow \infty$. The first line of eq. (12) becomes constant and the second and third lines reduce to

$$W(\omega, P, R) \propto \frac{1}{2P} \int dqq \times \begin{cases} 2P_2 q \\ P_F^2(R) - (P_2 - \frac{q}{2})^2 \end{cases} \text{ for } P_2 + \frac{q}{2} \begin{cases} \leq P_F(R) \\ \geq P_F(R) \end{cases} \quad (13)$$

$$2P_2 q \leq 2m|\lambda - \omega|, \quad |P_2 - \frac{q}{2}| \leq P_F(R)$$

$$|q^2 \mp 2P_2 q + P^2 - 2m(\omega - \lambda + \epsilon_F(R))| \leq 2Pq \quad \text{for } \omega \leq \lambda.$$

The dependence of W on R here is only contained in the local Fermi energy (8) so that eq. (13) can be employed for arbitrary potentials. Here and in the following we normalize W to attain the value $1/4\lambda$ at $\omega = P = R = 0$. Momentum transfers are limited to

$$0 \leq P \leq \begin{cases} 2P_F(R) + \sqrt{2m(\lambda - \omega + \epsilon_F(R))} & \omega \leq \lambda \\ P_F(R) + 2\sqrt{2m(\omega - \lambda + \epsilon_F(R))} & \omega \geq \lambda, \end{cases} \quad (14)$$

which provides also a small energy cutoff.

Results for $R = 0$ are shown in Figs. 1 and 2. One observes the well known quadratic behaviour around $\omega = \lambda$ which persists even for large P and which is fairly independent of P . However, contrary to the claims in refs. /2,8/, contributions from the polarization and from the correlation graphs are not strictly symmetric. This effect is strongly pronounced at small P . As a consequence of infinite quasiparticle lifetime at $\omega = \lambda$, $W(\omega = \lambda, P, R)$ must vanish. Finally, one observes that the nonlocality of W is rather important for all energies except $\omega \approx \lambda$, which calls in question the often made "innocuous assumption" /7/ of a local imaginary part of the optical potential.

Fig. 1 - Contour plot of $W(\omega, P, R = 0)$ for a zero range force. Energy E and energy transfer $P^2/2m$ are measured in units of the Fermi energy.

For zero momentum transfer, $W(\omega, P = 0, R = 0)$ can be calculated analytically ($\epsilon = \omega/\lambda$),

$$W(\omega, p=0, R=0) \propto \frac{1}{4} \begin{cases} 2 - \frac{1}{2}\epsilon^2 + \epsilon^2 \log \frac{|\epsilon|}{2} & -2\lambda \leq \omega \leq -\lambda/2 \\ 2 - \frac{1}{2}\epsilon^2 - (1+\epsilon)\sqrt{1+2\epsilon} + \epsilon^2 \log \frac{|\epsilon|(1+\sqrt{1+2\epsilon})}{2(1-\sqrt{1+2\epsilon})} & -\lambda/2 \leq \omega \leq 0 \\ (\epsilon-1)^2 & 0 \leq \omega \leq 2\lambda \\ \frac{3}{2}\epsilon^2 - 2\epsilon - 1 - \epsilon^2 \log \frac{\epsilon}{2} & 2\lambda \leq \omega \leq 4\lambda \\ (1+\epsilon)\sqrt{1+2\epsilon} - \epsilon^2 \log \frac{\sqrt{1+2\epsilon}+1}{\sqrt{1+2\epsilon}-1} & 4\lambda \leq \omega < \infty \end{cases} \quad (15)$$

which provides a good check of numerical accuracy. This quantity, together with the on shell value ($p^2/2m = \omega$), the P-integrated local equivalent of the nonlocal W,

Fig. 2a and 2b - Same as Fig. 1, but three dimensional (front and back views).

and the Glauber approximation are shown in Fig. 3. Here the Glauber result has been obtained by neglecting the Pauli principle, i.e. dropping the second and third θ -functions in eq. (7) and neglecting the hole energy $p_1^2/2m$ in the energy conserving

Fig. 3 - The imaginary part of the optical potential at $R = 0$ for various values of P and in the Glauber approximation.

δ -function. One sees that the local equivalent and $P = 0$ values are rather similar for positive energies but that the on shell value differs drastically for large energies. The Glauber approximation lies always above by virtue of the additional phase space gained by neglecting the Pauli principle.

In turning to finite size effects, W can be calculated analytically on shell, $\omega = P^2/2m + V(R)$,

$$W(\omega, \text{on shell}, R) \propto \begin{cases} 0 & 0 \leq \omega \leq \lambda - \epsilon_F(R) \\ \frac{1}{4} (P_F^2(R) - P^2)^2 & \lambda - \epsilon_F(R) \leq \omega \leq \lambda \\ \frac{2}{15} (2P_F^2(R) - P^2)^{5/2} / P + \frac{1}{3} P_F^3(R) P - \frac{7}{15} P_F^5(R) / P & \lambda \leq \omega \leq \lambda + \epsilon_F(R) \\ \frac{1}{3} P_F^3(R) P - \frac{7}{15} P_F^5(R) / P & \lambda + \epsilon_F(R) \leq \omega < \infty \end{cases} \quad (16)$$

The dependence on P^2 here is exactly the same as in infinite nuclear matter [2,10] but with λ replaced by the local $\epsilon_F(R)$. However, eq. (16) is not strictly the same result as one would employ the local density approximation, i.e. replacing λ by $\epsilon_F(R)$ everywhere since the regions of validity of the different branches do depend on the absolute Fermi energy λ as well.

Fig. 4 - The imaginary part of the on shell optical potential for different values of the local Fermi energy.

Fig. 4 shows the dependence of W on $\epsilon_F(R)$ or, in other words, on the radius R . The upper curve then corresponds to the nuclear interior and the lower ones to the surface. In assuming for instance a Woods-Saxon potential, for fixed energy, W is almost constant in the interior and falls off sharply at the surface. The local density approximation, on the contrary, would yield curves shifted to the left and, thus, violating the basic feature of $W(\omega = \lambda, P, R) = 0$.

IV - FINITE RANGE FORCE

Gaussian two-body effective interactions have typical ranges of 2.25 fm [14], i.e. $k_0/k_F = 0.625$. We therefore solved eq. (12) numerically for various ranges. The Gaussian $\exp(-2q^2/k_0^2)$ cuts off effectively the high momentum transfer contributions and, hence, forces W to decrease at high energy as shown in $W(\omega, \text{o.s.}, R = 0)$ of Fig. 5. The strength of the force, here again, has been adjusted to attain

Fig. 5 - Imaginary part of the optical potential on shell at $R = 0$ for various ranges k_0/k_F of the two-body effective Gaussian interaction.

$W(\omega = 0, P = 0, R = 0) = 1/4 \lambda$. The larger the range, i.e. the smaller k_0 is, the more concentrated is W around small energies.

For finite radii, W now depends also on the nuclear mass number via R_0 in the R' -integration. Fig. 6 therefore shows $W(\omega, \text{o.s.}, R)$ for a ^{40}Ca harmonic oscillator and $k_0/k_F = 0.625$ at various $\epsilon_F(R)$. A comparison with the zero range equivalent,

Fig. 6 - Imaginary part of the on shell optical potential for ^{40}Ca and various local Fermi energies.

Fig. 4, shows again the decrease of the optical potential in the surface and a concentration near small positive and negative energies.

Finally, we compare our exact calculations for finite range with those obtained by use of the Glauber approximation in Fig. 7. Here again, the additional false

Fig. 7 - Imaginary part of the on shell optical potential at $R = 0$ and range $k_0/k_F = 0.625$ compared with the Glauber approximation.

phase space gained by the neglect of the Pauli principle enhances W roughly by a constant amount for all energies.

V. SUMMARY AND OUTLOOK

We have applied semiclassical methods for the calculation of the imaginary part of the optical potential $W(\omega, P, R)$. Finite size effects have been incorporated by means of the nonlocal Fermi gas approximation and a finite range effective interaction. As results we found that the finite range of the force is responsible for the fall off of W at high energies; that the nonlocality of W is strongly pronounced especially for small P ; that the Glauber approximation yields values of W always too high by about a constant amount and that the strict local density approximation only roughly simulates finite size effects.

Further studies on this subject will be devoted to the calculations of the real part of the optical potential via subtracted dispersion relations, thus obtaining e.g. the correction to the Hartree-Fock potential and realistic level densities around the Fermi energy, effective masses and momentum distributions.
